Anthelmintic resistance of nematodes in small stock is seen worldwide and has become an important factor in the management of trichostrongylosis in the tropics. In France, 85% of goat dairy farms harbour benzimidazole-resistant nematodes. In South Africa, anthelmintic resistance has become a major problem in commercial sheep farming. One study reporting on 3 surveys indicated that more than 90% of the farms harboured Haemonchus strains that were resistant to at least 1 of the 4 anthelmintics tested and that between 60 and 78% of these strains were resistant to 3 anthelmintic groups. Similar anthelmintic resistance problems have been reported on commercial sheep farms in Zimbabwe and many other parts of the world. The available literature indicates little about the degree of resistance of nematodes to the commonly used groups of anthelmintics. This study was conducted within a radius of approximately 60 km of Mafikeng City, North West Province, South Africa, from January to March 2006.

Twelve smallholder sheep farmers, each rearing 40 or more sheep of the mixed breed (‘village sheep’) on communally managed rangelands, were included in this study. The predominant traits displayed by the sheep were those of Dorper and Merino. These sheep also graze freely, together with goats and cattle. During the 1st visit to the farmers, 4 groups of 10 sheep each, of different age and sex, were selected at random. All animals were ear-tagged, weighed and faecal samples were taken from each sheep rectally and transported in an ice-cooled box and stored in the laboratory at 4°C before analysis. One group was treated with albendazole (Prodose Green, Virbac Animal Health) as an oral drench at a dose of 7.5 mg/kg live mass. The 2nd group was treated with closantel (Prodose Yellow, Virbac Animal Health) as an oral drench at a dose of 5 mg/kg live mass. The 3rd group was treated with levamisole of all the 12 farmers included in the study. The efficacy percentage (FECR) was calculated according to Kettle et al. as the threshold at which an anthelmintic was considered effective by Boersema and Pandey. Poled faecal samples using the same amount of faeces from all the 40 treated animals after the 1st visit were incubated at 25°C in a Labotec incubator for 5 days and the 3rd-stage nematode larvae (L3) were harvested to differentiate which trichostrongylid genus was most dominant, using the method developed by Van Wyk et al.

Table 1 shows the anthelmintic efficacy, based on faecal egg count reduction (FECR %) of albendazole, closantel and levamisole of all the 12 farmers included in the study. The efficacy percentage shown in Table 1 based on FECR for albendazole varied from 68% to 96%. Levamisole based on egg counts showed an efficacy from 58% to 100% while closantel varied from 72% to 100%. On examination of the L3, the most prevalent genus was Haemonchus spp., followed by Oesophagostomum spp. and Trichostrongylus spp. Similar prevalence has been reported in communally grazed goats probably due to free grazing of sheep and goats on communal rangelands. In summer rainfall areas, Haemonchus has also been reported to be the most prevalent genus.
The efficacies of drugs used in the present study were generally above 80%, suggesting that the level of anthelmintic resistance may not be as high as on commercial sheep farms in southern Africa. The reasons for low resistance in communally grazed sheep is probably due to infrequent dosing by resource-poor farmers. There may therefore still be the prospect of slowing down the development of severe anthelmintic resistance against the commonly used groups of anthelmintics in communally grazed sheep in this region. However, on farm no. 3 the efficacies of albendazole and closantel were 68% and 72%, respectively while levamisole showed efficacies of 58%, 60% and 75% on farms 1, 3, 7 and 9, respectively (Table 1). This indicated presence of resistant nematode populations on those 4 farms. The anthelmintic resistance noticed in this survey in communally grazed sheep may be due to underdosing as a result of limited financial resources. This was especially so on farm no. 3 where it was mentioned on investigation that the animals were dosed with small amounts to both sick and healthy animals due to lack of money. On this farm the nematodes displayed resistance to all 3 drugs used in the study. The anthelmintic efficacy indicated on farm no. 3 to closantel might have been higher than 72%. Closantel has high efficacy only against blood-sucking parasites like Haemonchus spp. and hookworms, and not against Oesophagostomum spp. and Trichostrongylus spp. which were observed in the pre-treatment cultures. In addition to underdosing, emerging farmers often buy animals at auctions supplied by commercial farms on which anthelmintic resistance may be present, and in this way resistant nematode populations or strains may be disseminated. Levamisole displayed nematode resistant strains in 4 of 12 farms as compared with either albendazole or closantel which showed only 1 of 12 farms. Levamisole is the cheapest broad-spectrum anthelmintic in the Mafikeng region and because of this it is affordable by most communal farmers who frequently use it and this probably selects for resistant nematode strains, which might have been the case in this study. Similar levamisole resistance was reported on 2 of 10 communal goat farms.

The occurrence of anthelmintic resistance in the smallholder farming sector is a cause for concern. Steps should therefore be taken to prevent its further spread and to avoid the development of a situation as on commercial sheep farms in South Africa where resistance is common.

**ACKNOWLEDGEMENTS**

The author thanks the North West University Research committee for financial support, the communal farmers for their cooperation and the Animal Health Technicians for their assistance in faecal sample collection.
