Use of antibacterial nanoparticles in Endodontics

SUMMARY
Several root canal irrigants and medicaments are available to combat endodontic pathogens. However, evidence of complete elimination of these pathogens by the use of these solutions is not recorded in the literature. The possible development of resistant bacterial species is one of the problems related to the efficacy of the currently available irrigants and medicaments. In addition, the complex anatomy of the root canal system allows endodontic pathogens to be hidden in areas inaccessible to the action of the irrigating preparations. This is further enhanced by the protective layer that is formed by the remnants of pulp tissue, dentin powder and dead cells which inhibit the antibacterial activity of the root canal irrigants and medicaments. Antimicrobial nanoparticles show promising effect against resistant pathogens in pharmaceutical science as a result of their unique physio-chemical properties. Unlike traditionally used antimicrobial agents, these nanoparticles destroy bacterial cells through multiple mechanisms. The concept of using nanoparticles in endodontics as a new treatment modality was developed recently and their antibacterial efficacy against endodontic pathogens was evaluated by several researchers in many in vitro studies. This article reviews some of the currently available literature on laboratory studies that evaluated the efficacy of nanoparticles against endodontic pathogens.

Keywords: Endodontics, Antibacterial; chitosan; functionalized; nanoparticles; silver, magnesium, zinc.

ACRONYMS
ROS: reactive-oxygen species

INTRODUCTION
The world “nano” originated from a Greek word which means “dwarf”. The philosophy of nanotechnology was first illustrated in 1960 by Richard P. Feynman, a Nobel Prize winner, in his lecture “There’s Plenty of Room at the Bottom”. Since then, the concept of nanotechnology has been applied in numerous scientific fields such as physics, engineering as well as in the medical field. Nanotechnology is defined as a science that deals with the development of new materials with new properties and functions through controlling and restructuring of the materials on a nanometer scale of “less than 100 nm” and hence the name nanomaterials. The term is applied, according to the European commission, to “any natural, incidental or manufactured material containing particles, in an unbound state or as an aggregate or as an agglomerate and where, for 50% or more of the particles in the number size distribution, one or more external dimension is in the size range 1 nm – 100nm”.

Nanomaterials exist in different forms and shapes. They are categorized according to their dimensions into: zero dimension such as nanoparticles, one dimension such as nanorods, two dimensions such as thin films and three dimensions such as nanocones. They show increased chemical reactivity compared with their bulk form. The term nanodentistry is defined as “the science and technology of diagnosis, treating and preventing oral diseases, relieving pain, preserving and improving dental health using nanostructured material”. Nanodentistry is applied in different areas, for example: manufacturing of dental materials; prevention of oral diseases such as dental caries and periodontal disease; as therapeutic agents for the treatment of dentine hypersensitivity, oral cancer and endodontic diseases; in the technology of tissue engineering;
and as a diagnostic aid to identify certain diseases such as oral cancer. Currently the application of nanomaterial in endodontics is limited to a few studies that evaluated the antimicrobial properties of some nanomaterials in different forms against endodontic pathogens.

Endodontic diseases as a microbial infection
Microbial elements are the most common cause of pulpal and periapical pathosis. All endodontic infections are polymicrobial in nature with differences between the types of micro-organisms isolated from primary and secondary root canal infections. Microbiological studies have revealed more than 400 microbial species from endodontic samples.

Endodontic infection is eventually established as a biofilm. This form of microbial colonization inside the root canal system was initially discovered by Ramachandran Nair. Microbial biofilm is a surface-attached microbial community defined by Mohammadi *et al* as “a sessile multicellular microbial community characterized by cells firmly attached to a surface and enmeshed in a self-produced matrix of extracellular polymeric substance”. Endodontic biofilm is composed of 10-15% bacterial cells embedded in 85-90% of that extracellular substance.

Virulence of endodontic pathogens
The virulence and pathogenicity of endodontic microorganisms in a biofilm state are enhanced by several factors. In 2010, Kishen listed basic mechanisms which allow endodontic pathogens to resist the commonly used root canal irrigants and medicaments. These mechanisms are usually associated with the extracellular polymeric matrix, rate of bacterial growth, availability of nutrients and ability to adopt a resistant phenotype.

The extracellular polymeric matrix can play a major role in increasing the resistance of endodontic biofilm against root canal irrigants and medicaments. Amongst the factors contributing to this resistance are: the ability of the extracellular polymeric matrix to facilitate adhesion of the biofilm structure to the tooth surface and provide mechanical stability to the biofilm. The matrix is a source of nutrition during starvation conditions. Moreover, the close proximity of the bacterial cells within the biofilm structure facilitates microbial communications such as exchange of genetic information and communication between cells (quorum sensing) in the regulation of gene expression and microbial synergy. Additionally, the extracellular polymeric matrix was shown to decrease the penetration rate of antimicrobial agents.

Another factor associated with the high virulence of endodontic pathogens in a biofilm state is their ability to demonstrate dissimilar gene expression patterns compared with those microorganisms found in a planktonic state. As a result, microbial biofilm is found to be more resistant to antimicrobial agents.

Antibacterial mechanisms of nanoparticles
The use of nanoparticles as antimicrobial agents has recently attracted considerable attention in the medical field as a result of their superior antibacterial properties compared with those of other antimicrobial agents together with a low potential to produce microbial resistance. The antimicrobial activity of nanoparticles against different microorganisms differs from that of its original bulk state and may vary according to the different types of nanoparticles.

The efficacy of the nanoparticles to eliminate bacterial cells is attributed to the concurrent effect of two different mechanisms (Figure 1). One involves the binding of nanoparticles to the targeted bacterial cell membrane through electrostatic forces, causing an alteration in the membrane potential, depolarization and eventually loss of membrane integrity. This results in disturbance of major bacterial cell functions such as respiration, transportation of nutrients and disturbance of energy transduction, leading subsequently to bacterial cell death. The second mechanism includes the production of oxygen free-radicals such as reactive-oxygen species (ROS) that can influence survival of the bacterial cell by blocking the protein function, destroying DNA and resulting in excess radical production.

Antimicrobial efficacy of nanoparticles in endodontics
Different types of nanoparticles have been investigated recently in different forms in *in vitro* studies to evaluate their efficacy against endodontic pathogens. The nanoparticles used in these studies broadly can be classified into three categories according to their nature: metallic or inorganic, polymeric and bioactive non-organic nanoparticles.

Antibacterial efficacy of metallic or inorganic nanoparticles
The antibacterial effect of metallic or inorganic nanoparticles such as silver, magnesium and zinc oxide against endodontic pathogens have been evaluated in many *in vitro* studies. Among these, the antibacterial effect of silver nanoparticles was the most commonly considered in the literature.

Silver nanoparticles (Ag-NPs)

**Figure 1:** Diagrammatic representation of the antibacterial mechanisms of nanoparticles
(A) Toxicity through production of reactive oxygen species (ROS).
(B) Nanoparticles attach to bacterial cell membrane causing toxicity through cell membrane damage.
The antimicrobial properties of silver nanoparticles were first demonstrated by Jose Ruben et al.33 Silver nanoparticles have the ability to bind to the negatively charged part of the bacterial cell membrane, disturbing its functions such as permeability and respiration, causing leaking of the cytoplasmic content and eventually rupture of the bacterial cell. As a result, the nanoparticles will infiltrate inside the cytoplasmic content and interact with sulphur- and phosphorus-containing proteins such as DNA and RNA, causing further damage to the bacterial cell.33 Additionally, the silver nanoparticles release silver ions when in contact with an aqueous media, further disturbing the bacterial functions.33-37

Wu et al. evaluated the effect of silver nanoparticles in a concentration of 0.1% as an endodontic irrigant solution and as a gel in two different concentrations (0.02% and 0.1%) against Enterococcus faecalis biofilm.31 The solution did not cause any major change to the structure of E. faecalis biofilm. However, the use of silver nanoparticles in a gel form with a concentration of 0.02% had the ability to disrupt the structural integrity of the E. faecalis biofilm more than a 0.01% silver nanoparticle gel and thus decreased the number of viable bacteria.31

The antibacterial effect of silver nanoparticles as an intra-canal medicament in a paste form was evaluated by Buruniera et al.38 Three different carriers for silver nanoparticles were used in their study, namely; hydroxyethylcellulose polymer, carbomer polymer gel and polyethylene glycol. The antibacterial efficacy of these new materials was evaluated against different bacterial species such as E. faecalis, Pseudomonas aeruginosa, Streptococcus mutans, E. coli and Staphylococcus aureus. This study showed that the use of silver nanoparticles when loaded into different types of carriers had an antibacterial effect against the tested bacterial species. Additionally, the use of hydroxyethylcellulose polymer gel as a vehicle for silver nanoparticles provided the maximum homogeneity and fluidity as a carrier compared with the other materials and thus resulted in improved antibacterial properties.38

Silver nanoparticles may hold different surface charges and the effect of these variations on their antibacterial efficacy was evaluated by Abbasszadegan et al.39 The efficacy of three preparations having surface charges of neutral, negatively-charged or positively-charged against planktonic cells of E. faecalis was compared with that of

sodium hypochlorite and chlorhexidine. Positively-charged silver nanoparticles showed a minimal effect against the tested bacterial species. However, unlike with neutral and negatively-charged silver nanoparticles, sodium hypochlorite and chlorhexidine, the minimal antibacterial effect was still shown with the positively charged silver nanoparticles at lower concentrations. Additionally, some tissue inhibitors, such as dentine powder or the remnants of pulp tissue, that have the ability to inhibit the antibacterial effect of root canal medicaments,40 were shown to have no such effect on the antibacterial properties of the positively-charged silver nanoparticles even after 24 hours contact time. The study concluded that the antibacterial effects of different surface-charged silver nanoparticles, sodium hypochlorite, and chlorhexidine depended on their concentrations and the contact time.39

Furthermore, silver nanoparticles were shown to enhance the antibacterial properties of some intra-canal medicaments such as calcium hydroxide, as has been demonstrated by Alikhani et al. in their study which tested the effect of the combination on E. faecalis.41

The use of silver nanoparticles as an antimicrobial agent against endodontic pathogens shows promise. However, further investigation is required to evaluate any effect on the colour stability of the tooth structure, the dentine surface and possible cytotoxic actions on human cells.

**Magnesium-containing nanoparticles (Mg-NPs)**

Magnesium-containing nanoparticles were suggested for use as antimicrobial agents against endodontic pathogens due to their known antibacterial properties against gram-positive and gram-negative bacteria, spores and viruses.25 Magnesium-containing nanoparticles are either magnesium-oxide nanoparticles or magnesium-halogen-containing nanoparticles such as chlorine, bromine and fluorine.26-42 The antimicrobial properties of magnesium-containing-nanoparticles were thought to be due to multiple mechanisms. Similar to the common antimicrobial mechanisms of nanoparticles, magnesium-halogen-containing nanoparticles infiltrate inside the bacterial cell, resulting in a disturbance in the membrane potential. The penetration facilitated the DNA binding and lipid peroxidation effects of the nanoparticles, causing more destruction of the bacterial cell.43 Magnesium-oxide nanoparticles were found to be bactericidal when present in an aqueous form as a result of the action of superoxide anions that formed on the bacterial cell surface.44

The antibacterial efficacy of different concentrations of magnesium oxide nanoparticles (5 mg/L and 10 mg/L) and 5.25% sodium hypochlorite and 2% chlorhexidine against endodontic pathogens such as E. faecalis, S. aureus and Candida albicans was studied by Monzavi et al.30 The results showed no significant differences in the antimicrobial efficacies of the irrigant solutions used against the tested endodontic pathogens. However, the inclusion of magnesium oxide nanoparticles in an irrigant solution produced extended antibacterial activity when compared with sodium hypochlorite.30

**Zinc oxide nanoparticles (ZnO-NPs)**

Zinc oxide nanoparticles showed high antibacterial effectiveness,45,46 destroying microbial cells in a higher pH environment.47 The antibacterial mechanism of zinc oxide nanoparticles is similar to that of other types of nanoparticles, causing increased permeability of the cell wall membrane, a release of cytoplasmic content and cell death.48 The bactericidal effect of zinc oxide nanoparticles was shown to be related to size, the smaller the size the higher the antibacterial effect and the production of reactive oxygen species such as hydrogen peroxide when in contact with an aqueous medium.42,47,48,51 Additionally, zinc oxide nanoparticles can produce zinc ions inside the bacterial cell causing disturbances in its enzymatic system and the mechanism of amino acid metabolism, resulting in further damage.52 The antibacterial effect of zinc oxide nanoparticles has been shown to depend on concentration, higher levels resulting in the maximum antibacterial effect.42

The antibacterial and antibiofilm efficacy of zinc oxide nanoparticles against some endodontic pathogens such as E. faecalis were assessed by Kishan et al.32 It was shown that zinc oxide nanoparticles can reduce the colony forming units of E. faecalis in a biofilm state. The same antibacterial effect was evident when zinc oxide nanoparticles were incorporated into a resin based root canal sealer. Also shown was a 95% reduction in the ability of E. faecalis to adhere and form biofilm in a dentinal wall.24 Another study found that the thickness and structure of the E. faecalis biofilm was reduced and disrupted after 72 hours contact time with zinc oxide nanoparticles but concluded that zinc oxide nanoparticles have the ability to eliminate E. faecalis in a planktonic state but not in a biofilm state.23 Varying degrees of antibacterial effects against P. aeruginosa, E. faecalis, C. albicans, S. aureus and Kocuria rhizophila were shown when zinc oxide nanoparticles were incorporated into polyethylene glycol to form a creamy mix and used as an intra-canal medicament.48

Several studies also shown the antibacterial effect of using metallic nanoparticles against endodontic pathogens (Table 1). However, further developments in understanding their chemical structure are required if their antimicrobial properties are to be enhanced and further clinical testing of the antibacterial effects should be undertaken.

**Application of polymeric nanoparticles in endodontics**

**Chitosan nanoparticles**

Polymeric nanoparticles gained significant interest amongst researchers as a result of their biocompatible and antimicrobial properties.53 Chitosan nanoparticles (Cs-NPs) are one of the commonly investigated polymeric nanoparticles in endodontics. Chitosan is a natural polysaccharide54 that is obtained by deacetylation of chitin,55 one of the most abundant polysaccharides in nature that forms most of the external skeleton of arthropods such as crabs and shrimps.56 Chemically, chitin is composed of (1-4)-linked β-D-glucan and (1-4)-2-acetamide-2-deoxy-β-D-glucosamine.57 A modification in the structure of chitin in which the acetyl group is reduced by 40% to 35% by chemical hydrolysis in alkaline solution and high temperature produces a new chemical formula that consists of a copolymer of (1-4)-2-amino-2-deoxy-β-D-glucan and (1-4)-2-acetamide-2-deoxy-β-D-glucan which is known as chitosan.58

Although the antimicrobial efficacy of chitosan was assessed by several investigators, the antibacterial mechanism of chitosan has not yet been fully clarified. Several hypotheses have been postulated, based on its cationic nature. Chitosan with low molecular weight was considered to have the ability to penetrate the bacterial cell membrane and then to bind to the DNA, inhibiting its transcription and mRNA synthesis, while chitosan with high molecular weight was surmised to bind to the negatively charged components of the bacterial cell wall, forming an impermeable layer and blocking transportation into the cell. Another alternative hypothesis for the antibacterial mechanism of chitosan is thought to be as a result of its ability to bind to the negatively charged bacterial cell membrane, increasing its permeability and ultimately resulting in leaking of the cytoplasmic contents and bacterial cell death. Others postulated that as chitosan has the ability to chelate metals microbial growth was inhibited by reducing enzyme activity through metal chelation.

In endodontics, the use of chitosan nanoparticles as an antimicrobial agent was investigated against some endodontic pathogens (Table 3). Kishan et al. and Shertha et al. showed that chitosan nanoparticles can completely eliminate *E. faecalis* pathogens present in a planktonic state, and can cause a significant reduction of bacteria in the biofilm state. The presence of some tissue factors such as dentine powder, dentine matrix and remnants of pulp tissue within the root canal system was shown to inhibit the antimicrobial properties of some endodontic disinfectants. The effect of these tissue factors was evaluated by Shertha and Kishan against the antimicrobial properties of synthesized chitosan nanoparticles conjugated with rose bengal as photosensitizer. Remnants of bacterial tissue and dentine powder reduced the antibacterial efficacy of the conjugated solution in the first few hours. However, complete elimination of the tested bacteria before and after application of low energy photodynamic light was shown after 24 hours.

Chitosan nanoparticles were incorporated into a zinc oxide eugenol based sealer and were assessed for their antibacterial effect against *E. faecalis* biofilm on bovine root dentine treated by phosphorylated chitosan, chitosan conjugated with rose bengal and a combination of phosphorylated chitosan and chitosan conjugated with rose bengal, respectively. There was an inhibition of *E. faecalis* biofilm formation, the degree of inhibitory effects varying with the different treatment solutions used.

Bioactive glass nanoparticles

In 1971 a new material with antibacterial properties and that can bond to the bone structure was developed. The developed material consisted of 45% SiO2, 24% Na2O, 24.5% CaO and 6% P2O5 and was named Bioglass. The antimicrobial property of bioactive glass material was shown to be through its ability to: [i] release its ions when it came into contact with an aqueous medium, [ii] increase the surrounding pH [iii] increase the osmotic pressure around the bacterial cell causing inhibition of bacterial growth and [iv] to precipitate calcium and phosphate ions in the bacterial cell membrane, disturbing its functions. The use of 45S5 bioactive glass nanoparticles was found to produce better antibacterial effects against *E. faecalis* than micro-sized bioactive glass particles. However,
Zehnder et al. showed that calcium hydroxide is more effective than 20–60 nm sized bioactive glass nanoparticles against *E. faecalis.*

The use of bioactive glass nanoparticles as an antimicrobial agent as a replacement for the commonly used endodontic disinfectants is still an area of controversy as a result of the variation in results obtained by different studies regarding their efficacy against endodontic pathogens. More studies after further improvement in the synthesis of bioactive glass nanoparticles are needed.

**DISCUSSION**

The large number of nanoparticle materials available today provide multiple choices for their use in the medical field. Current endodontic research is focused on evaluating the antimicrobial properties of some nanoparticles as new agents against endodontic pathogens. Available studies show there is promise in the use of different types of nanoparticles as antimicrobial agents especially against persistent endodontic pathogens such as *E. faecalis.* Whilst it appears that some of the shortcomings, of traditional root canal irrigants and medicaments can be overcome, more *in-vitro* and *in-vivo* studies are needed to evaluate which nanoparticles are more appropriate for use as a root canal irrigant solution, intra-canal medication, or even bioactive root canal filling material, which is still an area of further investigation. Also, the antimicrobial effects of the nanoparticles need to be tested against a large variety of persistent endodontic pathogens. Indeed, more studies are needed to evaluate the biocompatibility, safety, cost and ease of use of these innovative materials.
