Shape analysis of the StW 578 calotte from Jacovec Cavern, Gauteng (South Africa)

The fossiliferous deposits within the lower-lying Jacovec Cavern in the locality of Sterkfontein yielded valuable hominin remains, including the StW 578 specimen. Because StW 578 mainly preserves the calotte, the taxonomic status of this specimen has been a matter of discussion. Within this context, here we employed high-resolution microtomography and a landmark-free registration method to explore taxonomically diagnostic features in the external surface of the StW 578 calotte. Our comparative sample included adult humans and common chimpanzees as well as one Australopithecus africanus specimen (Sts 5). We partially restored the StW 578 calotte digitally and compared it to extant specimens and Sts 5 using a landmark-free registration based on smooth and invertible surface deformation. Our comparative shape analysis reveals morphological differences with extant humans, especially in the frontal bones, and with extant chimpanzees, as well as intriguing specificities in the morphology of the StW 578 parietal bones. Lastly, our study suggests morphological proximity between StW 578 and Sts 5. Given the intimate relationship between the brain and the braincase, as well as the integration of the hominin face and neurocranium, we suggest that cranial vault shape differences between StW 578 and extant humans, if confirmed by further analyses, could be either explained by differences in brain surface morphology or in the face. Besides providing additional information about the morphology of the Jacovec calotte that will be useful in future taxonomic discussion, this study introduces a new protocol for the landmark-free analysis of fossil hominin cranial shape.

Significance:
- We provide further information on the enigmatic fossil specimen StW 578.
- We introduce a new approach for the morphological study of fossil hominin crania.
- We highlight morphological similarities between StW 578 and ‘Mrs Ples’.

Introduction

The palaeocave infills of the Sterkfontein Caves, which lie 50 km northwest of Johannesburg (South Africa), are well known for having yielded iconic fossil specimens, such as Sts 5 (‘Mrs Ples’) and StW 573 (‘Little Foot’). Fossiliferous deposits within the lower-lying Jacovec Cavern have provided additional hominin remains that are of particular interest; prominent among them is the StW 578 cranium. StW 578 was discovered in 1995 partly in situ in ‘Orange’ sediments (Loz7 coordinates: Y: -73582.546; X: 2878771.407; Z: 1450.909) that are composed of partially calcified breccia exposed in the roof of the eastern part of the Jacovec Cavern, and partly in collapsed breccia beneath. Because of the conflicting geomorphological scenarios of the infilling of the lower chambers in Sterkfontein13,14, determining a geological age for StW 578 is particularly challenging13,14. Absolute dating using cosmogenic nuclide burial methods originally provided an age of 4.02±0.27 Ma for the cranium.2

Together with the 3.67-million-year-old skeleton of StW 573, StW 578 represents some of the oldest evidence of human evolution in southern Africa.12 Because of its late Pliocene age, the StW 578 calotte (i.e. the top part of the cranium) is of great interest for reconstructing early hominin evolution. Late Pliocene fossiliferous deposits in the Jacovec Cavern coincide with an important radiation of the genus Australopithecus, with the emergence of Australopithecus afarensis, Australopithecus deyiremeda, Australopithecus bahrelghazali, and the ‘Burtele Foot’.13 For instance, previous studies of the postcranial assemblage from the Jacovec Cavern revealed an interesting mosaic of features, with the femur having a very long neck relative to a small head but a round-sectioned shaft, and with a clavicle (StW 606) that has morphological similarities to extant chimpanzees.13,14 Accordingly, StW 578 has the potential to contribute to our understanding of morphological variation and taxonomic diversity within Australopithecus in the late Pliocene.

Because the Jacovec calotte mainly preserves part of the calotte (Figure 1), along with fragments of the face and dentition, and a temporal bone (see Partridge et al.2; all initially cleaned and reconstructed by RJ Clarke), the taxonomic status of this specimen has been a matter of discussion. Indeed, in the original description, the authors refrained from attributing StW 578 to any species.2 Study of the cranial vault thickness and composition revealed close affinities with the Australopithecus specimens from Sterkfontein Member 4.3 However, Partridge et al. noticed that: posterior to this fossa the tympanic plate slopes strongly posteriorly as it does in Pan, and in this respect differs from all other Australopithecus temporals from Sterkfontein Member 4, which resemble more closely the human, vertically inclined tympanic plate.7,9-10

The dental and facial morphology and the presence of a metopic ridge on the frontal convinced Clarke and Kuman12 to classify this specimen as Australopithecus africanus rather than Australopithecus prometheus, teeth of which also occur in the Jacovec sample.
Given the significance of this specimen and ongoing debates, we virtually reconstructed the StW 578 calotte and compared its shape to those of extant humans, extant chimpanzees, and *Australopithecus africanus* (as represented by Sts 5). Besides introducing a new protocol for the shape analysis of fossil hominin crania, we also provide new insights into the morphology of the Jacovec specimen.

Figure 1: Virtual rendering of the StW 578 calotte in lateral right (top), superior (middle) and lateral left (bottom) views. Plaster used to physically reconstruct the cranium is in light grey and transparent.

**Material and methods**

**Comparative material**

Our comparative sample of extant specimens comprised mixed-sex samples of non-pathological adult humans (*Homo sapiens, n=6*) and common chimpanzees (*Pan troglodytes, n=6*). Extant human samples were obtained from the Pretoria Bone Collection of the University of Pretoria while extant chimpanzee samples were obtained from the Royal Museum for Central Africa in Tervuren (Belgium). Additionally, we included the *Australopithecus africanus* specimen Sts 5 that comes from Sterkfontein Member 4, dated to about 2.8–2.4 Ma based on faunal assemblages. Sts 5 is currently housed in the Ditsong National Museum of Natural History (South Africa). Parts of the outer bone table of Sts 5 remained in the breccia during the initial preparation by Broom, but this does not alter the overall shape of the cranial vault.

**Scanning and pre-processing step**

StW 578 and Sts 5 were scanned at the microfocus X-ray tomography facility of the Palaeosciences Centre at the University of the Witwatersrand, in Johannesburg (South Africa), at a spatial resolution of 66.6 µm and 75.0 µm (isotropic voxel size), respectively. A 3D model of StW 578 is available on MorphoSource. Extant humans and
chimpanzees have been similarly scanned at the South African Nuclear Energy Corporation in Pelindaba, South Africa, and at the Centre for X-ray Tomography of Ghent University (UGCT) in Ghent, Belgium, with a resolution ranging from 70.0 µm to 102.3 µm.

As a pre-processing step, all of the crania were oriented the same way with the opisthocranion and glabella aligned on a single transverse plane, and a new image stack reflecting the standardised orientation was generated using Avizo v9.0 (FEI Visualization Sciences Group Inc., https://www.fei.com/software/amira-avizo/). The same transverse plane was used to virtually cut the crania so that the superior part of the braincase (that is preserved in StW 578) could be separated from the rest of the cranum and studied. Finally, because we were interested in the external shape of the cranium only, we virtually isolated the external surface from the inner surface.

**Reconstruction of StW 578**

Before virtually reconstructing the StW 578 calotte, we removed the plaster using segmentation tools in Avizo v9.0 (STEP1, Figure 2A). We fitted a surface through StW 578 using the tool ‘Patch’ in Rhinoceros 3D v6.0.0 (STEP2, Figure 2B). The resulting surface (Figure 2B) was opened in Avizo v9.0 and the parts of the new surface that filled in the gaps between bones were manually extracted (Figure 2C) and merged with the initial surface using the tool ‘Flatten visible layer’ in Meshlab (STEP3, Figures 2D,E). This new surface was mirrored to reconstruct missing regions in the opposite side (Figure 2F). Finally, STEP2 and STEP3 were repeated (Figure 2G,H). Inferior portions of the parietal and frontal bones were still missing at this stage (Figure 2E). Because these regions cannot be reconstructed using existing bones, we preferred not to estimate them and thus systematically removed the homologous regions in all comparative specimens (see below).

Similarly, we removed the plaster in Sts 5 and the missing regions were virtually filled in by applying STEP2 and STEP3.

**Shape analysis**

We compared StW 578 to extant specimens and Sts 5 by using landmark-free registration based on smooth and invertible surface deformation. This approach has been previously applied to a number of craniodental and postcranial structures, including endocasts, enamel-dentine junctions, vertebrae and bony labyrinths and comparisons between the landmark-based and landmark-free approaches have revealed the ability of the latter approach for capturing geometric details and for statistical determination of geometric correspondence. Because the StW 578 calotte is partial, instead of using the whole surface to align specimens as in previous studies, we used four landmarks, i.e. glabella, opisthocranion, and two landmarks positioned on the external surfaces of the right and left parietal bones at the intersection of (1) a coronal plane positioned at three-quarters of the maximum length of the calotte and of (2) the transverse plane that was used for isolating the top of the calotte. Surfaces were aligned in position, orientation and scale using one surface that was randomly selected as a reference and by using the tool ‘Landmark Surface Warp’ (method: Rigid + Uniform Scale) in Avizo v9.0 which is based on the iterative closest point algorithm that minimises the root mean square distance between the points of each specimen to corresponding points on the reference. A template was deformed to extant specimens using Deformetrica v4. The extant specimens and Sts 5 were deformed to StW 578. Based on this computation, the parts of the frontal and parietal bones that are missing in StW 578 (Figure 2E) were systematically removed from the comparative extant and fossil specimens using an automated method. We then deformed another template to the extant comparative surfaces generated after this step and a global mean shape as well as taxon-specific mean shapes were rendered by colour maps.

**Figure 2:** Successive steps for the virtual reconstruction of the StW 578 cranium. The initial surface (A) has been wrapped using a patch (B) and the gaps reconstructed (C) and merged with the initial surface (D). To the end result of the first iteration (E), a mirror was applied (F) and the overall process repeated (G). The resulting surface is lacking lateral portions of the frontal and parietal bones (H) indicated by a star.
On the contrary, the frontal bones in StW 578 are more flattened than indicated by the white spots on both sides of the cranial vault in Figure 3B. The lateral part of the parietal bones in StW 578 is slightly more elevated as interspecific variation (Figure 3B–D). Compared with extant humans, the comparative specimens were investigated using topological mapping of the external surface. Along PC2, which represents 1.8% of the variation, the Sts 5 plot close to each other and closer to the extant human cluster in superior view. The colour bar represents the number of deformations. Both StW 578 and Sts 5 plot closer to the extant human cluster along PC1 that represents 93.2% of the variation. Here again, StW 578, extant humans and extant chimpanzees overlap along PC2 that represents 2.0% of the variation. We thus obtain similar results as in the first set of deformation that includes our reconstruction of the calotte, which tends to suggest that our reconstruction does not bias the result of the shape analysis.

Results

Figure 3A shows the PCA of the deformation-based shape comparison of StW 578 and extant and fossil comparative specimens. The two extant comparative groups are well discriminated along PC1, which accounts for 95.0% of the variation. Chimpanzees plot in positive space while extant humans plot in negative space. Along PC1, both StW 578 and Sts 5 plot close to each other and closer to the extant human cluster in negative space. Along PC2, which represents 1.8% of the variation, the two comparative groups and the fossil specimens mostly overlap.

The nature and extent of the differences between StW 578 and the comparative specimens were investigated using topological mapping of the superior part of the frontal bone and the lateral surface of the parietal bones. The regions that correspond to the missing bone in StW 578 were automatically removed from the extant specimens by using the results of the first set of deformations. We then computed a PCA using the deformation fields generated by this second set of deformation (Figure 4).

Discussion

Because of its fragmentary nature, the taxonomic and phylogenetic status of the StW 578 calotte remains debatable, although it has been recently assigned to *A. africana* by Clarke and Kuman. Within the limits of our sample, our comparative shape analysis reveals morphological differences with the cranial vault of extant humans, mainly located in the frontal bones and on the lateral surface of the parietal bones, and more dramatically with the cranial vault of extant chimpanzees. As such, our study further clarifies the polarity (i.e. derived or ancestral) of the cranial features identified in StW 578.

The hominin cranium is highly integrated. Frontal bone morphology reflects the integration of the bone structures of the upper face and anterior neurocranium. Within this context, the marked differences identified in the frontal bones of StW 578 and extant humans by our comparative shape analysis might reflect the primitive morphology of the upper face in *Australopithecus*. Indeed, the hominin face has experienced dramatic changes through time, with the earliest changes affecting primarily the canines and supraorbital regions (potentially associated to social interactions) and later modifications related to the masticatory apparatus and a transition from tough and hard to soft or processed food. On the other hand, within the frame of the hypothesis...
of modularity of the hominin face and neurocanium, we might consider the possibility that differences in the frontal bone could be the result of neutral evolution. Alternatively, this result might be explained by the influence of the frontal and temporal lobes on the morphology of the frontal bones. However, because significant reorganisation of the frontal and temporal lobes occurred in later hominins, this hypothesis is unlikely. Lastly, it is noteworthy that the extant human frontal bones are characterised by the presence of two bosses which are absent in fossil hominins. Nonetheless, these results are preliminary and will need to be further supported by future analyses including a large extent human sample.

The assessment of the cranial vault thickness variation in StW 578 demonstrated particularly thick parietal bones, which differs from the pattern of cranial thickness reported for extant humans and extinct chimpanzees (see Fig. 8 in Beaudet et al.9). The growth and development of the neurocranial bones is closely related to the growth and development of the brain (within the frame of the functional matrix hypothesis). Accordingly, we might hypothesise that differences in brain development and growth between StW 578 and extant humans could explain differences in the external cranial shape. Alternatively, it has been hypothesised that cranial bones may adapt to empty space and become thicker. Consequently, thickened bone in the parietal region and the resulting shape of the external surface of the braincase in StW 578 (this study) could be related to the morphology of the brain, and the lack of parietal expansion that is specifically found in modern human brains.

Finally, our study reveals close affinities of the shape of the external surface of the calotte of StW 578 and the *Australopithecus africanus* specimen Sts 5. At this stage, no conclusions on the taxonomic status of StW 578 could be drawn, as our sample, besides being relatively small, did not include any representatives of the taxon *Australopithecus prometheus*. However, unlike what is seen in the tympanic plate, our study of the external morphology of the StW 578 calotte does not reveal any substantial differences with another *Australopithecus* specimen, Sts 5, nor distinct proximity with extant chimpanzees. However, given the fact that the present preliminary results derive from a new protocol, our results should be carefully considered and future analyses should help clarify this question.

Acknowledgements

We are indebted to E. Gillissen and W. Wendelen (Tervuren), G. Krüger, and E. L’Abbé (Pretoria), L. Kgasi, H. Fourie and S. Potze (Pretoria), and S. Jirah and B. Zipfel (Johannesburg) for granting us access to fossil crania in their collections. For technical and/or scientific discussion/ collaboration we are grateful to: M. Carmen Arriaza (Johannesburg), G. Krüger (Pretoria), K. Kuman (Johannesburg), E. L’Abbé (Pretoria), A. Oettlé (Pretoria) and J.F. Thackeray (Johannesburg). We thank the Editor and two anonymous reviewers for their comments. We thank the DSI-NRF for sponsoring the Micro-XCT facility at UCT, the Centre of Expertise UGCT, and the DSI-NRF Centre of Excellence UGCT. We acknowledge the support of the AEOSEP+ program, the Claude Leon Foundation, the DSI-NRF Centre of Excellence in Palaeosciences and the French Institute of South Africa. The Ghent University Special Research Fund (BOFGenT) is acknowledged for the financial support of the Centre of Expertise UGCT (BOFEXP2017.0007). Major funding for the Sterkfontein excavations, microCT scanning work and research was provided by South African National Research Foundation grants (#82591, #82611, #98808, #129336) and by PAST. Opinions expressed and conclusions arrived at are those of the authors and are not necessarily to be attributed to the Centre of Excellence in Palaeosciences. Ethical clearance for the use of extant human crania was obtained from the Main Research Ethics committee of the Faculty of Health Sciences, University of Pretoria in February 2016.
