The impact of an electronic clinical decision support for pulmonary embolism imaging on the efficiency of computed tomography pulmonary angiography utilisation in a resource-limited setting

C Murthy; R Davis; E Irusen; C Murthy

Background. Pulmonary embolism (PE) is associated with high morbidity and mortality. Effective intervention requires prompt diagnosis. Computed tomography pulmonary angiography (CTPA) is sensitive and specific for PE and is the investigation of choice. Inappropriate CTPA utilisation results in unnecessary high radiation exposure and is costly. State-of-the-art electronic radiology workflow can provide clinical decision support (CDS) for specialised imaging requests, but there has been limited work on the clinical impact of CDS in PE, particularly in resource-constrained environments.

Objective. To determine the impact of an electronic CDS for PE on the efficiency of CTPA utilisation in a resource-limited setting.

Methods. In preparation, a PE diagnostic algorithm was distributed to hospital clinicians, explaining the combined role of the validated modified Wells score and the quantitative D-dimer test in defining the pre-test probability of PE. Thereafter, an automated, electronic CDS was introduced for all CTPA requests. Total CTPA referrals and the proportion positive for PE were assessed for three study phases: (i) pre-diagnostic algorithm; (ii) post-algorithm, pre-CDS; and (iii) post-CDS.

Results. The proportion of CTPAs positive for PE after CDS implementation was almost double that prior to introduction of the diagnostic algorithm (phase 1 v. 3, 17.4% v. 30.7%; p = 0.036), with a correspondingly significant decrease in the proportion of non-positive CTPAs (phases 1 v. 3, 82.6% v. 69.3%; p = 0.015) During phases 2 and 3, no CTPAs were requested for patients with a modified Wells score of ≤4 and a documented negative D-dimer, indicating adherence to the algorithm.

Conclusion. Implementing an electronic CDS for PE significantly increased the efficiency of CTPA utilisation and significantly decreased the proportion of inappropriate scans.

The safe and effective management of suspected PE, utilising a diagnostic algorithm that combines a validated clinical decision rule, the D-dimer test and CTPA, has been documented in various studies in the past decade. The combination of a low Wells score (≤4) and a negative D-dimer test has been shown to have a negative predictive value for PE of >99.5%, allowing patients with low clinical probability of PE to be spared CTPA and anticoagulants, while all other patients undergo definitive CTPA work-up.

Inappropriate utilisation of CTPA results in exposure to unnecessary high doses of ionising radiation and potential contrast-related anaphylactic reactions and is costly, particularly in a resource-limited setting.

The technical advances in diagnostic imaging over the past four decades have been paralleled by major developments in information technology. Filmless and paperless digital radiology departments, utilising electronic workflow, are now commonplace in well-resourced healthcare environments. In addition, digital imaging and electronic workflow are increasingly being introduced into resource-limited settings, where they have particular benefit in supporting remote reporting via teleradiology. Electronic workflow in radiology is driven by the radiology information system (RIS), which has a number of efficiency-enhancing features. These include the capacity for clinicians to request imaging studies electronically.
and to be guided in real time by embedded, evidence-based imaging algorithms during the ‘order entry’ process. Decision-support systems for advanced imaging are being implemented with increased frequency, but evidence of their effectiveness in reducing inappropriate imaging utilisation is limited. This is particularly true for resource-limited healthcare environments, where improved efficiency and cost-saving are pivotal.18

We therefore aimed to determine the impact of an electronic clinical decision support (CDS) for PE on the efficient utilisation of CTPA in a resource-limited setting.

Methods
Research site
The study was conducted in a 1 386-bed public-sector tertiary-level teaching hospital in the Western Cape Province of South Africa. The hospital performs approximately 180 000 radiological examinations annually and has a 40-slice MDCT scanner, with transfer of axial acquisitions to a dedicated workstation (Intellispace Portal, Philips Healthcare, USA). CTPA technique and diagnostic criteria for PE were constant across all study phases.

Study design
The study was conducted in three phases.

Phase 1 (baseline observation). This was a retrospective analysis before December 2012, which served to secure a reasonable quantum of data to represent the baseline observation.

Phase 2 (preparatory – clinical guideline without prompting). In December 2012, by way of preparation, a PE diagnostic algorithm was distributed to all hospital clinicians, outlining the combined role of the validated modified Wells score (Table 1) and the quantitative D-dimer test in defining the pre-test probability of PE (Fig. 1).

Phase 3 (CDS). In December 2013, coinciding with the implementation of electronic requests for diagnostic imaging, a CDS for PE was introduced, which appeared in real time whenever a CTPA was requested on the RIS. Clinicians were prompted to enter the Wells score and the D-dimer test result, thereby defining the pre-test probability of PE and hence the appropriateness of the CTPA request.

Results
Patients
A total of 603 CTPA examinations were performed across the three study phases; 424 patients (phase 1 n=149, phase 2 n=174, phase 3 n=101) were included in the analysis and, 179 were excluded (<18 years n=3, pregnant n=56, postpartum n=115, indications other than PE n=5) (Table 2). Patient demographics are presented in Table 3.

CTPA findings
The proportion of CTPAs positive for PE increased across the three phases (17.4% v. 22.4% v. 31.7%, respectively), with a corresponding decrease in the proportion of non-positive examinations over the same periods (82.6% v. 77.6% v. 69.3%, respectively) (Fig. 2).

Although the difference between phases 1 and 2 (17.4% v. 22.4%; p=0.267) and between phases 2 and 3 (22.4% v. 31.7%; p=0.128) was not significant, the trend was clear and the overall difference between phases 1 and 3 (17.4% v. 31.7%; p=0.014) was significant.

Discussion

In this first study of its kind in a resource-limited environment, we have shown that the phased implementation of a computer-prompted pre-test probability scoring system for PE almost doubled the efficiency of CTPA and significantly decreased the proportion of inappropriate scans.

Both our 17.4% positive CTPA yield for PE in phase 1 and our 30.7% phase 3 yield are substantially higher than the pre-intervention (17.4% v. 30.7%) compared very favourably overall 82% increased CTPA yield from baseline documented in recent similar studies[21-25] in substantially higher than the pre-intervention (3 in phase 1 and our 30.7% phase 3 yield are number of inappropriate scans.

The success of the PE CDS bodies well for similar initiatives in a broad range of clinical settings, since numerous clinical algorithms are well suited to electronic prompting in radiology with a similar potential impact on clinical efficiency.

Strengths of our study were the two prospective study phases and the comprehensive availability of patient data on the RIS. A minor limitation was the lack of definitive diagnostic work-up, with either subtraction angiography or ventilation-perfusion scanning, of the small proportion (6.3%) of patients with an equivocal CTPA. Lastly, this study had limited power in distinguishing between the three phases and had limited external validity.

Since ours was a derivation cohort, we recommend validation of the results in a larger, prospective cohort. However, this intervention demands rigorous compliance and mindful application of the clinical decision rule. Hospital education programmes should include existing diagnostic guidelines, thereby encouraging its implementation.
